

This page describes the Rayleigh corrections made for non-absorbing gases. The next page describes the more complicated problem of absorbing gases.

A radiative transfer numerical model is used to solve the vector (polarized) radiative transfer equation for non-absorbing atmospheric gases only. The radiative transfer model includes atmospheric multiple scattering, polarization, and sea surface roughness modeled analytically by a Cox-Munk slope distribution with an added analytical wave shadowing function. The Cox-Munk slope distribution as used is azimuthally isotropic (no dependence on wind direction); therefore only the relative angle between Sun and viewing direction matters. This greatly simplifies the Fourier decomposition seen in Eq. (3) of Wang (2002). The radiative transfer model is described in Ahmad and Fraser (1982).

Wind Speed and Surface Reflectance Effects

Background sky reflectance by the rough sea surface is accounted for as part of the Rayleigh correction. Some sensors (CZCS, SeaWiFS, OCTS) can be tilted to avoid looking at glint near the Sun's specular direction. Other sensors (MODIS, VIIRS, MERIS, OLI) do not tilt and therefore must account for specular reflection.

Wind speed and surface glint corrections are computed as described in Wang (2002): Run the numerical model to compute a look up table (LUT) of TOA Fourier components $L_r^m(\lambda, \theta_s, \theta_v, \tau_{Ro}, W)$ (his Eq. 3) for the following conditions:

- The sensor wavelength bands (e.g., bands centered at 412, 443, 490, 510, 555, 670, 765, 865 for SeaWiFS). The radiative transfer model is run using band-averaged optical thicknesses (rather than running at high-wavelength resolution, and then averaging the L_r values over the band response functions to get the nominal band values of L_r for a particular sensor).
- 45 Sun zenith angles θ_s from 0 to 88 deg by 2 deg
- 41 viewing nadir angles θ_v from 0 to 84 deg by roughly 2 deg
- Rayleigh optical thickness τ_{Ro} for standard sea level atmospheric pressure $P_o = 1013.25\text{hPa}$ (1013.25 millibar).
- 8 wind speeds $W = 0, 1.9, 4.2, 7.5, 11.7, 16.9, 22.9$ and 30.0 m/s. (These wind speeds correspond to convenient spacing in the mean square slopes of the sea surface according to the Cox-Munk equation $mss = 0.00512W$: $mss = 0.0, 0.01, 0.02, 0.04, 0.06, \dots$ for $W = 0, 1.9, 4.2, 7.5, 11.7, \dots$) Linear interpolation is used for values between these wind speeds.

The Rayleigh optical thickness $\tau_{Ro}(\lambda)$ at 1 atmosphere of pressure, P_o (1013.25 hPa), temperature of 288.15K, and a CO_2 concentration of 360 ppm is given by Eq. (30) of Bodhaine et al. (1999):

$$\tau_{Ro}(\lambda) = 0.0021520 \left(\frac{1.0455996 - 341.29061\lambda^{-2} - 0.90230850\lambda^2}{1.0 + 0.0027059889\lambda^{-2} - 85.968563\lambda^2} \right), \quad (1)$$

Figure 1: The Rayleigh optical thickness and depolarization ratio based on Bodhaine et al. (1999).

where λ is in micrometers. These values and the corresponding Rayleigh depolarization ratio $\rho(\lambda)$ are shown in Fig. figure1. (At the scale of this figure, the Bodhaine values are almost indistinguishable from the values given by the formula of Hansen and Travis (1974) (see Eq. (15) of Bodhaine et al. (1999)), which were used in earlier calculations.)

The Rayleigh LUTs for L_r contain the I , Q and U Stokes vector components in reflectance units, as a function of wind speed and geometry. The Stokes vector V component for circular polarization is assumed to be zero. There is a separate LUT for each wavelength.

During image correction, the wind speed W for a given pixel comes from NCEP 1 deg gridded data, interpolated to the image pixel.

Pressure Effects

The Rayleigh optical thickness at the time of the observation depends on the number of atmospheric gas molecules between the sea surface and the top of the atmosphere. The number of molecules is directly proportional to the sea-level pressure P . Thus the Rayleigh optical thickness at any pressure P is given by

$$\tau_R(P, \lambda) = \frac{P}{P_o} \tau_{Ro}(P_o, \lambda).$$

The TOA L_R is then computed by Eq. (5) of Wang (2005) and subsequent equations:

$$L_R[\tau_R(P, \lambda)] = L_R[\tau_R(P_o, \lambda)] \frac{1 - \exp[-C(\lambda, M)\tau_R(P, \lambda)M]}{1 - \exp[-C(\lambda, M)\tau_R(P_o, \lambda)M]}, \quad (2)$$

where

$$M = \frac{1}{\cos \theta_s} + \frac{1}{\cos \theta_v} \quad (3)$$

is the geometric air mass factor for the total path through the atmosphere. $C(\lambda, M)$ is a coefficient that is determined so that Eq. (like section 2) gives the best fit to $L_R[\tau_R(P, \lambda)]$ as computed by an extremely accurate atmospheric radiative transfer model when run for values of sea level pressure $P \neq P_o$. Numerical simulations show that this coefficient can be modeled as

$$\begin{aligned}
 C(\lambda, M) &= a(\lambda) + b(\lambda) \ln(M) \\
 a(\lambda) &= -0.6543 + 1.608\tau_R(P_o, \lambda) \\
 b(\lambda) &= 0.8192 - 1.2541\tau_R(P_o, \lambda).
 \end{aligned}$$
